Received 8 August 2014; accepted 18 August 2014
Available online 31 July 2015

Abstract This is a consensus document of the Sociedad Española de Infectología Pediátrica, Sociedad Española de Reumatología Pediátrica and Sociedad Española de Ortopedia Pediátrica on the aetiology and diagnosis of uncomplicated acute osteomyelitis and septic arthritis.

A review is presented of the aetiopathogenesis and pathophysiology of acute osteoarticular infection defined as a process with less than 14 days of symptomatology, uncomplicated, and community-acquired. The diagnostic approach to these conditions is summarised based on the best available scientific knowledge. Based on this evidence, a number of recommendations for clinical practice are provided.

En este documento se revisan la etiopatogenia y la fisiopatología de la infección osteoarticular aguda en niños, considerada como aquella no complicada, de origen comunitario, que presenta una evolución inferior a 14 días, así como la aproximación clínico-diagnóstica a estas entidades, basándose en las mejores evidencias científicas disponibles. En función de dichas evidencias, se aportan una serie de recomendaciones para la práctica clínica.

Introduction

Osteoarticular infection (OAI) is particularly important because the musculoskeletal system of the child is constantly growing. Thus, an infection that affects the growth cartilage or epiphyseal plate may cause abnormalities in bone development with the corresponding sequelae. The three participating societies, the Sociedad Española de Infectología Pediátrica (Spanish Society of Paediatric Infectology [SEIP]), the Sociedad Española de Reumatología Pediátrica (Spanish Society of Paediatric Rheumatology [SERPE]) and the Sociedad Española de Ortopedia Infantil (Spanish Society of Childhood Orthopaedics [SEOP]) consider that it is very important to have a consensus document gathering all the published scientific evidence on uncomplicated OAs in the paediatric age group. This document covers both acute osteomyelitis (AOM) and septic arthritis (SA), and is essentially a review of the evidence on haematogenous community-acquired infections with an acute course (<14 days). We have also developed a set of recommendations that we present with their corresponding levels of evidence and grades of recommendation (Table 1).1

This consensus is not intended to replace the clinical judgement or to serve as a protocol to be applied to all children with this type of infection, and its contents are probably not the only suitable approach to OAs in children.

A future document will address the treatment of OAs.

Epidemiology

OAs are most frequent in the paediatric age group, with a prevalence of 22 cases per 100,000 children in developed countries.2 Fifty percent of cases occur in children younger than 5 years, and at least 25% in children younger than 2 years.3 The annual incidence of SA is estimated at 4 cases per 100,000 children,4 and that of AOM at 2–13 cases per 100,000 children,5,6 with the latter being twice as frequent. When it comes to neonatal osteomyelitis, the reported incidence in intensive care units is of 1–3 cases per 1000 admissions.7 The male to female ratio is 1.2/3.7.7

The literature describes a 2.8 fold increase in the number of OAM cases in the past 20 years while the number of SA cases has remained stable,5,6 a trend that may be due to advances in diagnostic techniques. There are several predisposing factors that promote the development of OAs, which are detailed in Table 2, although most OAs occur in children with no underlying disease.

Usually, AOM is unifocal and affects the metaphyses of long bones, especially femur (30%), tibia (22%) and humerus (12%),7,8 while involvement of the calcaneus or the pelvis is less frequent. The reported prevalence of AOM of the hip ranges between 1% to 11%, and it usually affects older children.9,10 Multifocal infections are more frequent in newborns (NBs), with a prevalence of up to 40%, in children with immunodeficiencies, and in children infected by methicillin-resistant Staphylococcus aureus (MRSA).9,10

When it comes to SA, over 90% of the cases are monoarticular6 and they affect lower limb joints most frequently (70% of cases), especially the knee (35–40%), hip (25–30%), ankle (13–15%), elbow (10%) and shoulder (5%).3,4,11

OAs of the spine may cause discitis, and most frequently affect the lumbar region7,12,13 and children younger than 5 years as intervertebral discs are vascularised from the adjacent vertebra (a vascularisation that disappears later
o). Cases of discitis described in adolescents may be due to avascular necrosis as opposed to true infection. Ver-
tebrae involve in 1–2% of cases, especially in children
more than 8 years of age.

AOM and SA (osteoarthritis) coexist in up to 30% of chil-
dren (especially NBs [70% of cases] and children less than
18 months of age), mainly at the shoulder or hip due to the
presence of intra-articular metaphyses.\textsuperscript{7,8,12}

## Aetiology

### Most frequent bacterial agents

The most frequent microorganism in every age group is
\textit{Staphylococcus aureus} (\textit{S. aureus}). In NBs and up to 3
months of age, \textit{Streptococcus agalactiae} and enterobacteria
(especially \textit{Escherichia coli}) are also important. Between 3
months and 2–5 years of age, the most frequent causative
agents are \textit{S. aureus} and \textit{Kingella kingae}, while from this age
onward most infections are caused by \textit{S. aureus} and, to a
lesser degree, by \textit{Streptococcus pyogenes}\textsuperscript{14} (Table 3).
When arthritis is found in sexually active adolescents, \textit{Neisseria
gonorrhoeae} should also be considered.\textsuperscript{11} Table 3
presents the bacteria associated with different risk factors.

## Pathogenesis

### Septic arthritis

Most cases of SA are caused by the haematogenous spread
of microorganisms to the synovium. Bacterial endotoxins in
the joint space stimulate the release of cytokines, leading
to leucocyte migration and the destruction of the cartilage
matrix within the joint.\textsuperscript{11} When it comes to the hip and
shoulder, this effect is compounded by the damage caused by
the vascular collapse that results from the increased intra-
articular pressure exerted by the accumulation of pus.
Infection may also spread from adjacent foci, especially in cases of osteomyelitis in infants. Lastly, the joints may become infected from puncture wounds, arthrotomies or the injection of drugs in the joint space, with the last two causes being rare.

**Acute osteomyelitis**

The most frequent source of infection is the haematogenous route. AOM originating from open fractures, puncture wounds, animal bites or contiguous infections such as sinusitis, tooth infections or mastoiditis are less frequent.

In the context of bacteremia, infection spreads to long-bone metaphyses due to their abundant blood supply: the slow blood flow in their capillary loops and the presence of endothelial gaps allow the passage of microorganisms. The bacteria proliferate, forming colonies that obstruct the capillary lumina, hindering phagocytosis and antibiotic penetration. The foci of metaphyseal infection become the source of bone marrow and cortical bone infection. The presence of transphyseal vessels in NBs and infants provides a vascular connection between the metaphysis and the epiphysis, promoting the development of osteoarthritis in these age groups. Since metaphyseal capillaries atrophy at 18 months, joint involvement is rare in later ages except for joints with intracapsular metaphyses like the hip or the shoulder.

*S. aureus*, the most frequent pathogen in OAls, has numerous surface proteins responsible for its adhesion to host tissues. Once adhesion has been achieved, the ability to form biofilms or small colonies contributes to the persistence of the infection. In addition, *S. aureus* can produce proteins that inhibit chemotaxis, leukocidins (Panton-Valentine leukocidin [PVL]) that destroy leukocytes and modulins that can induce lysis in osteoblasts.

**Clinical manifestations**

**General symptoms**

The duration of symptoms of an acute OAI is less than 14 days; when the duration is longer is considered subacute or chronic. This duration is arbitrary, albeit widely accepted, and additional radiological, clinical or pathological anatomy criteria may be important to better define the infection.

The initial symptoms of OAI may be nonspecific, such as irritability, general malaise, decreased appetite or decreased activity. Patients, especially NBs and young infants, may not always present with fever, which is found in 62–72% of cases and it is more frequent in SA.

**Local symptoms**

The main clinical features are focal pain and decreased range of motion or functional impairment, which are found in 56–95% and 50–92% of cases, respectively. Frequently, the patient develops an antalgic posture. When the infection is localised in the lower limbs or the axial skeleton (spondylodiscitis, sacroiliitis), the patient limps or refuses to walk. Other local symptoms will depend on the site of infection:

- In addition to pain, AOM may present with swelling, warmth, and even erythema if the infection has spread to the subperiosteal space and subcutaneous tissue.
- When infection in SA is superficial, for instance at the knee, it manifests with pain, swelling and warmth, and seldom with erythema. However, when it is deep, as occurs in hip infections, there is no swelling, warmth or redness, and clinical suspicion arises from the report of pain in the ipsilateral groin, thigh or knee combined with a painful reduction of mobility in the joint, especially in internal rotation: the child usually displays an antalgic position of the hip, with sustained flexion, external rotation and abduction.
- Patients with spondylodiscitis and sacroiliitis avoid walking and standing, and assume a characteristic tripod position. A high degree of suspicion is required to diagnose OAI at these locations.

**Neonatal period**

The most benign and frequent form manifests without systemic symptoms or fever, and the typical presentation consists of irritability, decreased appetite and pseudoparalysis of the affected limb with pain upon movement. There is a severe form that presents with bacteremia and typical signs of sepsis that occurs more frequently in preterm NBs. There are also cases of AOM secondary to cephalo-haematoma or invasive monitoring.

**Sickle-cell disease**

These children are at high risk of developing AOM and SA due to microvascular occlusions. The clinical presentation of AOM is similar to that of a vaso-occlusive crisis and the differential diagnosis can be quite challenging. Infection episodes seem to be associated with higher fever and longer duration of pain at a single location.

**Physical examination**

The physical examination is key to establishing diagnostic suspicion and subsequently assessing the course of the disease. It consists of:

- Detailed general examination, starting from the contralateral side.
- Observation of spontaneous posture.
- Assessment of the musculoskeletal system, which may be performed by means of the pGALS (paediatric gait, arms, legs, spine), a validated and easy-to-implement tool. Table 4 presents a simplified version of the pGALS.
- Comparison of the affected side with the healthy contralateral side to identify differences in posture, size, temperature and colour.
- Assessment of the gait.
Table 4  The pGALS (paediatric gait, arms, legs, spine) assessment for detecting musculoskeletal symptoms.

The Fabere manoeuvre can be useful in the assessment of the sacroiliac joint (http://www.aeped.es/sites/default/files/documentos/cojera.pdf).

We want to highlight that: (1) Pinpoint tenderness is typical of AOM; (2) manoeuvres for the assessment of sacroiliitis, such as the Fabere test, are not useful in young children because they are uncooperative, and (3) erythema supra-adjacent to a joint is a sign of soft-tissue involvement and usually does not correspond to a true case of arthritis.
Diagnosis of osteoarticular infections

Laboratory and microbiological diagnosis

Clinical suspicion, history taking and physical examination are the first steps to achieve the diagnosis. Additional tests will help confirm the diagnosis.

- Complete blood count and acute phase reactants: there is frequently an increase in the erythrocyte sedimentation rate (ESR) and the levels of C-reactive protein (CRP) and other acute phase reactants, although these are nonspecific findings. These parameters are not usually very elevated except at advanced stages. The combined elevation of CRP and ESR is very useful for the initial assessment, as OAI is improbable if these values are not elevated soon after admission. Leukocytosis is rarely found.

- Blood culture: a sample must always be collected to attempt the identification of the causative microorganism, although its diagnostic yield is less than 50%.

- Analysis of joint fluid: arthrocentesis or the puncture of the joint space to collect synovial fluid should be performed whenever SA is suspected and before initiating antibiotic treatment. Thus, the cytological and biochemical analysis of synovial fluid, while nonspecific, can help narrow down the diagnosis (Table 5). Usually, a white blood cell count above 50,000 cells/mm³ with polymorphonuclear cell predominance is suggestive of an infectious aetiology, as it is a reduced glucose level (<50% of the plasma level).

Identification of the causative agent is the gold standard for SA diagnosis, although it is only achieved in 20–80% of cases. Ideally, all the fluid or tissue collected in a sterile tube (swabs should not be used) should be sent as soon as possible to be processed for gram staining and culture. The direct inoculation of joint fluid in a blood culture bottle increases the yield, especially when K. kingae is suspected (possibly the most frequent agent in negative-culture OAI). Polymerase chain reaction (PCR) allows the identification of this and other bacteria that grow poorly in culture and in infections that have been previously treated with antibiotics. To date, we have not found biological and clinical characteristics of SA that would allow the prediction of the involved pathogen, except for younger age, milder symptoms and lower levels of inflammatory markers in children infected by K. kingae. Additional specimens for acid-fast staining, culture and PCR should be collected for the diagnosis of tuberculous arthritis; in this case a synovial biopsy may also be required.

- Joint puncture: some authors believe that it is not needed before starting empirical antibiotic therapy in AOM, reserving it for patients with unfavourable outcomes, those with abscesses or with chronic osteomyelitis. However, some facilities perform it regularly and without complications, with or without ultrasound aid and it leads to the identification of the microorganism in 40–60% of the cases.

- Tuberculin test (or immunological-based tests): it should be requested when osteoarticular tuberculosis is suspected, although this disease usually has a subacute or chronic course.

The diagnosis of other, less frequent infectious causes may require additional specific tests (PCR and serology).

Imaging tests

- Plain radiography (X-ray). X-ray is still relevant when an OAI is suspected and it is useful in ruling out other pathologies such as fractures or tumours. In cases of AOM, X-rays are usually normal in the first 10–14 days, and then reach a sensitivity of 82% and a specificity of 92% at 2–3 weeks from the onset of symptoms. Some typical radiological features of AOM are osteolysis, osteopaenia and periosteal elevation or cortical thickening. In vertebral osteomyelitis or spondylodiscitis, the X-ray may show a reduction in the intervertebral space and a lateral X-ray may show vertebral erosions. In cases of SA, it may show an enlargement of the joint space and the soft tissues in the acute phase.

- Ultrasound. This is a very useful technique in SA due to its low cost, accessibility and high sensitivity. It detects joint effusion in 95% of cases, although the ultrasound findings are not pathognomonic for infection. It is especially relevant in the diagnosis of SA of the hip and shoulder due to the difficulty of a clinical diagnosis and it can be very helpful in guiding arthrocentesis. Doppler ultrasoundography can show increased blood flow, although their absence does not rule out SA.

- In cases of AOM, it helps detect subperiosteal or soft-tissue abscesses, but a normal scan does not rule out this infection. It can also be used in guiding aspiration. In the early stages, a positive finding in Doppler ultrasound examination of the bone suggest the presence of AOM.

![Figure 1](image)

Figure 1: Algorithm for the diagnosis of osteoarticular infection. Ultrasound is very helpful in guiding the initial diagnosis of septic arthritis but not as helpful in the diagnosis of osteomyelitis (see text). In septic arthritis of the hip or shoulder, joint decompression should be achieved as soon as possible (see text). Puncture and drainage can be guided by ultrasound or computed tomography. ESR: erythrocyte sedimentation rate, MRI: magnetic resonance imaging, PCR: polymerase chain reaction.

<sup>a</sup> Most frequently involved bacteria: S. pyogenes, Salmonella, N. meningitidis and N. gonorrhoeae.<br/>

<sup>b</sup> Some metaphyseal and epiphyseal tumours, like Ewing’s sarcoma, may invade the joint and cause joint effusion.

ANA, antinuclear antibodies; ERA, enthesitis-related arthritis; F, female; JIA, juvenile idiopathic arthritis; M, male; MRI: magnetic resonance imaging; PCR, polymerase chain reaction.
- **Computed tomography (CT).** Although it does not detect specific changes in the early stages, it can show soft-tissue oedema and deep extraosseous abscesses, facilitating puncture and drainage. It can be useful in the diagnosis of infections of the pelvis or with subacute and chronic courses, as it can detect bone sequestrations. Nevertheless, at present it is not used often due to the high amount of radiation involved.

- **Magnetic resonance imaging.** It is probably the best imaging test for the diagnosis of AOM and it is quite useful in the investigation of lesions of the axial skeleton and the pelvis. If the location of the lesion is known, it has a high sensitivity (97%) and specificity (92%). However, it may be difficult to differentiate other lesions that manifest with tissue oedema, such as tumours, fractures, bone infarction or bone changes secondary to concussion, although this diagnostic issue does not usually arise in clinical practise. Due to its cost, the need of sedation in young children and its lower availability, its use is often restricted to cases with a protracted or complicated course. The main indications for MRI are: confirmation of osteomyelitis, suspicion of complications (abscess/sequestration), vertebral or pelvic osteomyelitis, inconclusive ultrasound or scintigraphy results in OAI and SA cases refractory to antibiotic therapy.

- **Bone scintigraphy.** Although it has a low specificity, it is a very sensitive technique for locating the site of osteomyelitis, sacroiliitis or spondylodiscitis and for ruling out multifocality. Lower sensitivities have been found in young infants and neonates, and in infections by very virulent bacteria such as community-acquired (CA) MRSA. Technetium-99 is the preferred isotope due to the ease and quickness of the technique but it may result in false positives in the presence of other conditions with osteoclastic hyperactivity, such as fractures, tumours, bone infarction or post-operative lesions. Gallium-67 or labelled leucocyte scanning are believed to be more specific in active infections, but these techniques are more complex and obtaining the images may take up to 48 h.

- **Other techniques.** Single-photon emission CT or bone marrow scintigraphy with sulphur colloid may have some diagnostic indications for this pathology in the future.

While in most instance the AOM diagnosis should be confirmed with an imaging test other than a simple radiograph, in mild clinical illnesses that respond well to treatment further imaging may not be necessary. **Fig. 1** presents an algorithm for the diagnosis of OAI.
Osteoarticular infections

Differential diagnosis

Differential diagnosis of septic arthritis

Table 6 shows the most relevant differential diagnoses for monoarticular SA as well as their significant specific characteristics. Skin and soft-tissue infection or knee bursitis must also be considered. On rare occasions, SA is polyarticular and must be differentiated from rheumatic diseases, such as systemic lupus erythematosus, rheumatic fever or juvenile idiopathic arthritis, and from reactive arthritis secondary to certain infections.

Differential diagnosis of acute osteomyelitis

The differential diagnosis takes into consideration: (1) cellulitis and soft-tissue infections, especially myositis (sometimes associated to AOM); (2) fractures and other traumatic injuries; (3) osteochondrosis, usually manifesting with local inflammatory signs with no increase in acute phase reactants and normal radiological appearance; (4) benign tumours (osteoid osteoma, osteoblastoma); (5) malignant tumours, such as Ewing sarcoma (soft tissue involvement, fever and general malaise), neuroblastoma (bone metastasis) and osteosarcoma; (6) septic inflammatory osteitis, such as chronic recurrent multifocal osteomyelitis (CRMO); (7) Langerhans cell histiocytosis, which may be clinically and radiologically indistinguishable from osteomyelitis; (8) lymphoproliferative disorders that may be mistaken for AOM due to the presence of pain and inflammation, and (9) osteonecrosis due to vaso-occlusive crises in sickle-cell disease. In the rare cases that there are multiple sites of infection (Staphylococcus aureus, Bartonella, Coxiella), the differential diagnosis must include CRMO.

A bone biopsy and histological examination should be performed if the diagnosis is uncertain, and the specimen must be processed for culture and PCR determination of rarer microorganisms, such as fungi and mycobacteria. Table 7 presents the most relevant recommendations of this consensus along with their grades of evidence.

Conflicts of interest

The authors have no conflicts of interest to declare in relation to what is expressed in this document.
