The recent advances in molecular genetic diagnostics have led to the identification of two so far undescribed congenital endocrine syndromes. The patients had been followed in the department for pediatric endocrinology at the University Children’s hospital Berlin and their clinical symptoms had been observed for a long time. However, only the possibility of molecular genetic study made it possible to clarify the cause of the complex syndromes.

**THE POMC-DEFICIENCY SYNDROME**

Two patients were identified with isolated ACTH-deficiency. The diagnosis was made in the girl in the first month, because her older brother had died at the age of 4 months from liver failure caused by cirrhosis following prolonged jaundice and cholestasis. Postmortem adrenal hypoplasia was recognized and immunostaining of his pituitary revealed the absence of ACTH staining cells, while immunostaining for all the other pituitary hormones was normal. In the girl jaundice and cholestasis developed in the third week of life and Cortisol and ACTH measurements resulted in levels below the detection limits. With hydrocortisone replacement jaundice and cholestasis resolved rapidly and no adrenal crisis was observed. Thus the diagnosis of isolated ACTH-deficiency was made. The second patient, a boy, presented at the age of 1 year with hypoglycemia during febrile convulsions, after a period of postnatal hypoglycemia had resolved after one week with glucose infusions. The endocrine work-up of this patient surprisingly revealed complete ACTH-and cortisol deficiency and he was substituted with hydrocortisone subse-
The molecular basis of new paediatric endocrine syndromes: POMC, LHX3 and NKX 2.1 deficiency syndromes

- During the follow-up at the department for paediatric endocrinology a dramatic and early onset increase in body weight leading to a BMI of 30 and 29 at the ages of 4 and 6 years. Height in both children was above the 97th percentile. Moreover it was recognized that both children had red hair (fig. 1a and b). The etiology of this syndrome of ACTH deficiency, red hair pigmentation and obesity remained obscure, until the molecular basis of the obesity in the agouti overexpressing mice was clarified. These mice overexpress the agouti protein which is an antagonist to the natural POMC-cleavage peptide alpha-MSH at the MC1 and MC4 receptor, but not at the MC2 (ACTH) receptor of the adrenal gland (fig. 2).

Since alpha MSH and ACTH, the natural ligand to the MC2 receptor derive from the POMC molecule, we put forward the hypothesis that the association of symptoms observed in the two children was caused by a mutation of the POMC-gene. Sequencing of the gene identified a mutation in both patients: The boy was homozygous for a C 3804 A mutation in exon2 and the girl was compound heterozygous for a G 7013 T and a C 7133 del mutation in exon3. Since all mutations abolish the production of alpha MSH and ACTH the symptoms of obesity (MC4 receptor), red hair pigmentation (MC1 receptor) and ACTH deficiency (MC2 receptor) could be explained. Since the description we were able to identify homozygosity or compound heterozygosity for mutations (C3804 A, C 7133 del, 7102 ins GG) in 3 other patients with exactly the same association of symptoms. Moreover we were able to perform a prenatal diagnosis of heterozygosity in a subsequent pregnancy.

of the mother of the female patient. This girl is now one
year old and had no adrenal insufficiency or red hair, neit-
her did she develop obesity. Moreover the clarification of
the molecular cause of their obesity enables the pharma-
coological intervention.

THE LHX3 SYNDROME

Three children of five children of consanguinous par-
ters suffering from combined pituitary hormone deficiencies
had been followed for several years at our department. The
first child, a daughter was diagnosed with central hy-
pothyroidism and growth hormone deficiency at the age of
nine months after the family had immigrated to Germany
and in the second female child the diagnosis of β-TSH and
growth hormone deficiency was established by clinical
diagnosis at the age of three months. Both girls also deve-
loped hypogonadotropic hypogonadism. The third child –
as well as the fifth child- is healthy, while diagnosis of cen-
tral hypothryoidism and growth hormone deficiency was
made at the age of two weeks in the fourth child, a boy.
All three affected children were substituted with l-thyroi-
dine, growth hormone and at the age of puberty the two girls
didn’t develop obesity, while the boy is still pre-
pubertal with an age of 9 years. The peculiar finding in all
affected children was a short neck and an impaired ability
to rotate the head (fig. 3). MRI -imaging studies had reve-
